20

The object is achieved by a method and a system according to the appended claims.

Summary of the invention

30

35

replacing said stored password hash value with said new password hash value.

Impersonation means that the DBA steals the identity of an user, and is able to act in the name of the user, preferably while the user is unaware of the impersonation. Even though the DBA still can read the encrypted password and replace it, the attempt to impersonate a user will be detected and measures can be taken.

calculating a control value of said trigger, such as a hash value; and

With the method above the intrusion is detected when a user tries to log in, since the hash value of the users password will not match. In order to detect intrusion earlier the method can preferably comprise the further step of comparing for each active user having access to sensitive data, the hash value of the current login password with the currently stored password hash value, whereby said step is performed after every change of the database content by said user.

Also according to the invention a impersonation prevention system for a relational database preventing an administrator impersonating another user, which database at least comprises a table with at least a user password, wherein said password is stored as a hash value, said system comprises:

trigger means, which trigger at least said calculation means for calculation of a new hash value of said password when an administrator alters said table through the database management system (DBMS) of said database; and

Such a system will overcome the risk for a DBA impersonating a user with all the advantages as the method previously described.

For exemplifying purposes, the invention will be described to embodiments thereof illustrated in the attached drawing, wherein:

30

Referring to fig. 1, a schematic view of the components in a granular protection system of a database are shown. The central repository of the data is the database. In this case it is a relational database. An example of such a database is Oracle8®, manufactured and sold by Oracle Corporation, USA. The data is stored in

tables, which are interrelated with each other and the tables comprises columns and rows. The database can also hold other information such as information about the structure of the tables, data types of the data elements, constraints on contents in columns, user data such as password, etc. The database is operated through a database management system (DBMS). A DBMS is imposed upon the data to form a logical and structured organization of the data. A DBMS lies between the physical storage of data and the users and handles the interaction between the two.

An user normally does not operate the DBMS directly, the user uses an application which in turn operates with the DBMS. Maintenance work is performed by a database administrator (DBA), which connect direct to the DBMS. An administrator is a role with certain privileges given to a person, i.e. a special kind of user. For instance, the privileges can include allowance to add new users or read data, and normally the administrator is allowed to unrestricted use of the database. Thus, an administrator is allowed to manipulate data, manage users and other operating tasks of a database. A user, in contrast to an administrator, is normally only allowed to manipulate the actual data in the database, and often only some of the data. Which data an user can manipulate is regulated by the users permissions, which are set by the administrator.

In order to protect the data in the database an access control system (ACS) interacts with the DBMS in order to protect data from being exposed to users without the necessary rights. The access control system in the preferred embodiment could for instance be the commercially available system "Secure.Data", a system provided by the applicant. The ACS provide encryption and decryption of data, authentication of users and provides means for the security administrator (SA) to provide different users or user groups with different privileges

Thus, an user accesses the database through an application, which in turn uses the DBMS to access the database. During the access, the ACS interacts in real time with the DBMS to permit or deny the access attempt. But, a DBA will always have access to the database. However, in order to protect the information for the DBA, sensitive data is encrypted by the ACS. But, there is risk that the DBA would impersonate an user in order to gain access to decrypted data. This is as described prevented by a system and a method according to the invention. Such a system according to a preferred embodiment will now be described.

15 The system provides calculation means for
calculating a hash value of a user password. The first
time a user is created by the SA, the SA gives the user a
user name and a user password. The user name and password
is stored in the database. In order to not reveal the
20 password to for example a DBA, the password is stored as
a hash value. The calculation means is preferably
implemented in the ACS.

The system further comprises trigger means for triggering the calculation means for calculation of a new hash value. The trigger means survey the actions of a administrator and triggers an action when the administrator attempts to change the password of a user through the DBMS. Then the calculation means are triggered and a new hash value is calculated.

Referring to fig. 2, a preferred embodiment of a method according to the invention will now be described. Initially, when the SA creates a new user or changes the password of a user, the hash value of the password will be stored in a table. In a first step S1, a trigger is added to the table where user passwords are stored. The trigger triggers an action as soon as a database administrator alters the table. Preferably the trigger is

implemented in the DBMS data language. The trigger could register each occasion an alter is made on the table, and preferably separate those alters that concern user passwords. Another possibility is to read the log or
 5 cache of the DBMS and search for altering statements. The trigger function could be implemented as a daemon process.

In another step, S2, depending on if a trigger has been fired, a new hash value of the same password is
 10 calculated. The new hash value differs from the previously stored hash value. This hash algorithm is not accessible by the DBA and is preferably executed within the ACS.

Then the new calculated hash value replaces the
 15 stored hash value in a step S3.

In another embodiment of the method according to the invention the integrity of the trigger is also checked at regular intervals. Otherwise, the DBA could deactivate the trigger temporarily in order to impersonate a user
 20 without being discovered. Therefore a snapshot is preferably created of the trigger. This could be done by creating a checksum or a hash value of the trigger which could be stored separately or in conjunction with the trigger.

The DBA attack will be discovered either when a user
 25 logs in or during the attempt. If the hash value of a user password is compared with the stored hash value and the comparison results in a mismatch, the user will not be able to log in. But, preferably after every action by
 30 a user, which has access to sensitive data, the hash value of the users login password should be compared with the stored password. In that way the DBA attack will be discovered sooner.

The invention has been described above in terms of a
 35 preferred embodiment. However, the scope of this invention should not be limited by this embodiment, and alternative embodiments of the invention are feasible, as
